## Background/Aims

Practice testing is one of the best-researched learning techniques in the educational sciences and has shown considerable promise in boosting student learning across diverse settings (Yang et al., 2021). However, surprisingly little research has evaluated the effectiveness of selftesting in demanding math courses in higher education (Carvalho et al., 2022; Wong et al., 2017), which are often plagued by high dropout rates and low performance (Benden \& Lauermann, 2022). Moreover, self-testing in mathematics is conceptually different from fact recall in that it is about knowing how to solve a problem rather than memorizing the solution. The present study thus examined (a) the effectiveness of self-testing via two online practice opportunities in a gateway math course, and (b) the extent to which different subgroups of students benefitted from self-testing.

## Method

Economics/business administration students ( $N=188,59 \%$ female) enrolled in a gateway math course participated in the study. Students participated in three 30-minute online self-testing sessions, each covering content from the previous 3-to-4 weeks. A daily self-testing app was introduced in the second half of the course to practice content from the first half. Students received immediate corrective feedback. Students' gender, prior performance, motivational beliefs, personality traits, time preferences, and course goals were assessed at the beginning of the semester (Table 1).

## Results

First, OLS regressions revealed that self-testing with the practice tests improved students' exam scores by about 5 points (of 90). A double-selection regression (Belloni et al., 2014) was then used to select relevant control variables, reduce a potential omitted variable bias, and avoid overfitting in the prediction of exam performance; the self-testing effect remained significant but decreased to 2.5 points (Table 2). Use of the daily self-testing app had a significant effect on students' exam performance in the simple OLS regression, but not in the post-double-selection regression.

Second, heterogeneous practice effects were examined for a set of LASSO-selected control variables (Table 2). A post-LASSO regression showed that risk-averse students, those
who planned repeated practice, and students with a higher math self-concept were most likely to benefit from self-testing. Notably, students' gender, achievement goals, and personality traits did not contribute to differential practice effects. Only one significant interaction emerged for selftesting via the daily app; higher open-mindedness corresponded to greater benefits from selftesting.

Finally, a quantile regression revealed that self-testing via the practice tests was most effective for students who obtained a lower end-of-term exam grade (see Figure 1).

## Discussion

Our results show that self-testing is a promising intervention to support students' academic success in demanding math courses. This intervention appears to support those who need it most-low-performing students. In contrast, students' gender, achievement goals, and personality traits were not associated with differential self-testing effects, which supports the broad applicability of self-testing. The modality of implementation, however, warrants further consideration, as course-embedded practice tests were more effective than a daily self-testing app.

New data from an ongoing follow-up study will also be presented, which uses withinperson randomization to assess content- and time-specific effects of self-testing on later performance.

Note. The table shows the number of observations (N), means, and standard deviations (SD) per variable for the full sample, including incomplete cases, and for a subsample with complete data. Supplemental analyses show that the reported regression results are unlikely to be affected by selection bias. MAD = The app 'a matrix a day'. * indicates a dichotomous variable. These are equal to one if the realization is equal to the name of the variable and zero otherwise (e.g., Female $=1$ if students are female and zero otherwise).

Note. Heteroskedasticity-robust standard errors are shown in parentheses. MAD = The app 'a matrix a day'. Columns 2 to 4 show the post-double selection regression (PDSR) results for each algorithm (LASSO, random forest, and xgBoost). For all three columns, we used a double selection process to select relevant control variables for (i) the outcome and (ii) the practice variables. $\dagger$ Includes high school GPA, advanced math in HS, last math grade in HS, international degree program, sports management program, minor, work to finance studies, semester of study, retaking course, self-concept, planned number of practice tests. $\ddagger$ Includes high school GPA, advanced math in HS, last math grade in HS, international degree program, minor, semester of study, retaking course, self-concept, attainment value, performance-approach, performance-avoidance, risk, present bias. § Includes female, high school GPA, international degree program, mastery-avoidance, performanceapproach, agreeableness, openness, neuroticism, risk, discount factor, present bias. Columns 5 and 6 show simple selection results using LASSO, including interaction terms with the practice variables. Column 5 includes all possible interactions between the practice variables (see Table 1) and the additional variables listed below the practice variables in Table 1, while column 6 focuses on EVT beliefs. $\propto$ and $\Gamma$ Include, apart from the interactions, the high school GPA.
${ }^{*} \mathrm{p}<0.1 ;{ }^{* *} \mathrm{p}<0.05$; *** $\mathrm{p}<0.01$

Figure 1: Quantile Regression Results

(iv) MAD percentage

Note. The panels show the coefficient estimates mentioned in the headings from (i) to (iv) across quantiles and estimated based on a quantile regression on the final exam points. The coefficients across quantiles were estimated either including (a) the intersection of all machine-learning selected control variables or (b) the union of all selected control variables. The solid red horizontal line shows the value obtained in an equivalent OLS regression, and the dotted red lines show the $90 \%$ confidence bounds of the OLS estimate. The shaded areas identify the $90 \%$ confidence bounds of the quantile regression estimates. The standard errors of the quantile regression coefficients were calculated using a wild bootstrap procedure with 5,000 replications.
